Summary

Bleeding and thrombotic disorders are major complications affecting patients with chronic kidney disease (CKD). Exposure of circulating platelets to uraemic toxins and contact with artificial surfaces during dialysis induce platelet abnormalities and alter the platelet proteome. We hypothesised that these changes may be subsequent to changes in the composition and/or regulation of the platelet transcriptome. In this study, we investigated the circulating platelets of 10 CKD patients (i.e. five chronic haemodialysis patients and five stage 4 CKD uraemic patients) and five age- and sex-matched healthy subjects. We observed an alteration of the platelet messenger RNA (mRNA) and microRNA transcriptome in CKD patients. Impaired in uraemic platelets, the levels of some mRNAs and of most microRNAs appeared to be corrected by dialysis, which is consistent with a beneficial effect of dialysis and a mRNA regulatory role of platelet microRNAs. Reduced in platelets of uraemic patients, phosphatidylcholine transfer protein (PCTP) and WD repeat-containing protein 1 (WDR1) were found to be regulated by microRNAs, the latter of which involving hsa-miR-19b, a microRNA increased in platelets of uraemic patients and involved in platelet reactivity. These results suggest that an alteration of microRNA-based mRNA regulatory mechanisms may underlie the platelet response to uremia and entail the development of platelet-related complications in CKD.

Introduction

Cardiovascular disease (CVD) is a major cause of morbidity and mortality among patients suffering from chronic kidney disease (CKD) and is the leading cause of death in patients on chronic haemodialysis (1–3). The high prevalence of established traditional risk factors in CKD patients, such as lipid disorders, diabetes and hypertension, as well as non-traditional risk factors (e.g. oxidative stress, inflammation) and platelet abnormalities (4–7), may contribute to accentuate the risks of CVD and thrombotic complications. Patients with CKD suffer from complex haemostatic disorders. On one hand, uraemic patients present abnormalities of primary haemostasis (i.e. platelet dysfunction and impaired platelet-vessel wall interactions) and increased risk of bleeding (8–10). On the other hand, several studies have shown that platelet reactivity is increased in CKD patients undergoing haemodialysis (11), which is associated with increased risk of thrombo-embolic events (12–14). CKD is thus characterised by a delicate balance in which deficient haemostasis paradoxically coexists with enhanced risk of thrombosis, and in which platelet abnormalities may play an important role.

Playing a critical role in the maintenance of haemostasis, platelets may directly contribute to cardiovascular complications, such as myocardial infarction and stroke, in CKD patients (8–10). Although devoid of a nucleus and lacking genomic DNA, circulating human platelets retain as much as 45% of the Refseq genes in the form of mRNAs (15), inherited mainly from their megakaryocyte progenitor cells (16). Several reports confirmed that platelet mRNAs can support de novo protein synthesis (17), including a recent study reporting the translation and secretion of the metalloproteinase inhibitor Timp 2 by activated platelets (18). Weyrich et al. (19) had previously demonstrated that synthesis of Bcl-3 by activated platelets participate in blood clot retraction, while Evangelista et al. (20) reported that de novo synthesis of cyclooxygenase-1 counteracts the suppression of platelet thromboxane biosynthesis by aspirin.

Proteomic analyses of platelets revealed that their protein expression profile is altered in CKD patients (21, 22). Although reticulated platelets sustain changes in terms of platelet volume, morphology and RNA content in subjects treated with haemodialysis (23, 24), whether the mRNA profile of platelets is altered in CKD and haemodialysis patients remains unknown. These observations prompted us to formulate and verify the hypothesis that the biochemical conditions (e.g. increased uraemic toxins) prevailing in patients with CKD, leading or not to end-stage kidney failure and dialysis, might negatively affect the transcriptome of circulating platelets, which is constituted mainly of mRNAs and of non-coding microRNAs.

Thrombosis and Haemostasis 108.4/2012
Materials and methods

Recruitment of the subjects

After obtaining informed consent, 10 CKD patients (n=5 chronic haemodialysis patients and n=5 stage 4 CKD patients, later referred as dialysis and uraemic patients, respectively) were recruited to participate in this study, which was approved by our Institutional Human Ethics Committees. Five age- and sex-matched healthy subjects with normal renal function were recruited as control group. For all participants, data on demographics, medical history and current pharmacological treatment regimen were collected, as detailed in Table 1. Approximately 400 ml of venous blood was collected from each subject using collection bag containing sodium citrate as anticoagulant. For dialysis patients, blood collection was performed immediately prior to dialysis treatment. Haematological and biochemical data were recorded for each subject and are summarised in Table 2.

Purification of blood platelets

Venous blood was centrifugated at 170 g for 15 minutes (min) to obtain platelet-rich plasma (PRP), which was cleared by another centrifugation at 600 g for 10 min and filtered through leukocyte depletion filters (Pall corporation, Port Washington, NY, USA). Platelets were collected by centrifugation at 1,500 g for 15 min and subjected to negative selection based on magnetic cell sorting using human CD45+ depletion kit (EasySep, Stemcell technologies, Reston, VA, USA). Approximately two thirds of purified platelets were lyzed in TRIzol solution (Invitrogen, Carlsbad, CA, USA) for RNA extraction, whereas the remaining platelets were flash-frozen in a dry-iced ethanol bath and stored at −80°C for subsequent enzymatic and Western blot experiments, as described previously (25).

RNA extraction and analysis

Platelet total RNA was extracted using TRizol (Invitrogen) according to the manufacturer’s protocol. Purity of the platelet preparations was assessed by reverse-transcription (RT) polymerase chain reaction (PCR) amplification of the leukocyte marker CD45 and platelet marker GPIIIa, as previously described (25). For microarray analysis, 1.5 μg of total RNA from each subject were pooled together for each cohort. Pooled total RNA was purified further using the RNeasy Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer’s protocol. The integrity of the total RNA samples was assessed by Bioanalyzer 2100 (Agilent Technology, Santa Clara, CA, USA) prior to mRNA and microRNA profiling.

Data are expressed as mean ± standard deviation (SD). Dialysis treatment was complemented with the same pharmacological treatment for all the patients, which comprised Darbepoetin and Iron Sucrose (anaemia treatment), 1-OH-Vitamin D and furosemide. Other agents: phosphate binders (calcium or non calcium), sodium polystyrene and allopurinol.

Microarray profiling and analysis of platelet mRNAs

mRNA profiling was performed through the CRCHUQ Genomics platform (CHUQ research center/CHUL, Quebec, QC, Canada) using Human Gene 1.0 ST DNA BioChip (Affymetrix, Santa Clara, USA), according to the manufacturer’s protocol. Analysis of mRNA profiles from Human Gene 1.0 ST microarray data was performed on protein–coding genes. Differentially expressed mRNAs were defined as mRNAs two-fold more (or less) expressed among the uraemic or dialysis patients as compared to healthy subjects.

Quantitative real-time PCR (qPCR) experiments

Expression of selected genes of interest was assessed by qPCR using Quantitect SYBR green PCR kit (Qiagen) on a StepOnePlus Real-Time PCR system (Applied Biosystem, Foster City, CA, USA). The ΔΔCt method (26) was used to perform the relative quantification of the target genes using GAPDH mRNA as the reference gene. Expression of microRNAs of interest was assessed by qPCR using the miSCRIPT PCR system (Qiagen). MiR-191 was used as the reference for relative quantification, since this microRNA displayed no variation in expression.
levels in our microarray data; similar observations were reported by Nagalla et al. upon analysis of platelet miR-191 from 17 healthy donors (27). All results were normalised to the average expression level obtained for the healthy subjects group, and arbitrarily set at 1.

Microarray profiling and analysis of platelet microRNAs

MicroRNA profiling was performed by Exiqon microRNA profiling service (Vedbaek, Denmark). The three samples (healthy, uraemic and dialysis platelets total RNA pool) were labelled using the miRCURY™ Hy3/Hy5 Power labelling kit and hybridised on the miRCURY™ Locked Nucleic Acid (LNA) Array (5th generation arrays covering microRNA registered in miRBase 15.0 – Sanger Institute, Cambridge, UK [28]). Differentially expressed microRNAs were defined as microRNA whose expression level was two-fold higher or lower than that observed in healthy subject group. Predicted mRNA targets of differentially expressed microRNAs were determined using miRecords (http://mirecords.biolead.org) (29). 

Reporter gene activity assays

HEK293 cells (2 x 105) were plated in 24-well plates 24 hours before cotransfection with a pGeneClip (Promega, Madison, WI, USA) construct expressing pre-miR-599 or pre-miR-19b-1 (2.5 to 250 ng DNA) and a psiCHECK (Promega) reporter construct, in which the 3’UTR of phosphatidylcholine transfer protein (PCTP) or WDR1 (100 ng DNA) was inserted downstream of the Rluc reporter gene, using Lipofectamine 2000 (Invitrogen). A pGeneClip-Neg vector (30), encoding a short hairpin RNA (shRNA) directed against a deleted region in Rluc mRNA, was used as a negative control. Forty-eight hours later, cells were harvested and protein extracts were prepared for measurement of Renilla luciferase (Rluc) and Firefly luciferase (Fluc) activities, essentially as described previously (30).

Statistical analyses

Results were expressed as mean ± standard deviation (SD). Statistical analyses were performed using InStat 3 software (GraphPad). For all analyses, a p < 0.05 was considered as statistically significant.

Results

Recruitment and characteristics of the subjects

In this study, we characterised the mRNA and microRNA transcriptomes of circulating platelets from a total of 10 CKD patients: (i) five patients suffered from end-stage renal disease (stage 5) and
were treated by chronic haemodialysis (dialysis patients) (Table 1), whereas (ii) the other five patients suffered from stage 4 CKD (uraemic patients), the last stage before renal replacement therapy (e.g. haemodialysis or renal transplantation), which corresponds to an eGFR ranging from 15 to 29 ml/min/1.73m² (31).

Table 1 shows chronic medication use in study participants. Although the dialysis patients were treated for anaemia, their red blood cell count, haemoglobin content and haematocrit remained relatively lower than the other subjects (Table 2). None of the subjects presented obvious platelet disorders, as platelet count and platelet mean volume were within a normal range.

Differential platelet mRNA profile of uraemic and dialysis patients

The previously reported alteration of the protein expression profile in circulating platelets of CKD patients (21, 22) prompted us to examine the impact of CKD on the platelet mRNA transcriptome. Microarray profiling of platelet mRNAs on pooled RNA samples revealed that the majority of platelet mRNAs is not markedly affected in uraemic and dialysis patients, as compared to the healthy subjects. A total of 23 and 17 mRNAs are differentially expressed in platelets from dialysis and uraemic patients, respectively, as compared to healthy subjects. Seven mRNAs are differentially expressed in both patient groups.
Analysing those differentially expressed platelet mRNAs among our uraemic and dialysis patient cohorts (Fig. 1B), seven genes showed a similar deregulation in both cohorts of CKD patients, whereas 15 genes were altered specifically in dialysis patients.

Validation of selected platelet mRNAs by qPCR analyses

Next, we wished to confirm the differential expression observed for selected mRNAs, on an individual basis, by qPCR. Four genes were selected based on their different patterns of expression and potential relevance to platelet function. Assessment of their mRNA expression levels by qPCR accurately reflected those obtained by microarray profiling (Table 3), thereby confirming the validity of our microarray approach using pooled RNA samples. As expected, the level of two of them, serine incorporator 1 (SERINC1) (Fig. 2A) and lysophosphatidic acid receptor 4 (LPAR4) (Fig. 2B), was reduced by ∼50% in CKD patients, as compared to healthy subjects. In contrast, the mRNAs encoding for oxysterol binding protein 2 (OSBP2) and metallothionein 1X (MT1X) were upregulated in CKD patients (Fig. 2C and D, respectively). Although in some cases statistical significance could not be reached, the differential mRNA expression assessed by microarray and qPCR displayed similar tendencies.

Alteration of the platelet microRNA profile in uraemic patients

The conditions associated to CKD may affect the ability of platelets to synthesise or mediate the function of microRNAs, a family of small non-coding RNAs known as key regulators of mRNAs. To verify that possibility, we performed Dicer activity assays in vitro using protein extracts prepared from purified circulating platelets.

qPCR data are provided as mean ± standard deviation. * p<0.05; ** p<0.01 versus healthy subjects (Mann-Whitney Test).
We observed no significant changes in the ability of platelet Dicer to produce microRNAs among the uraemic or dialysis patients, as compared to healthy subjects (see Suppl. Fig. 1A, available online at www.thrombosis-online.com), although we noted a certain degree of inter-individual variations. A similar observation was made when monitoring the expression level of the ribonuclease Dicer and of its cofactor TRBP (see Suppl. Fig. 1B, available online at www.thrombosis-online.com), which are known to mediate platelet microRNA biogenesis.

Using a similar approach, we also assessed the functionality of microRNA effector complexes, composed of the ribonuclease Argonaute 2 (Ago2), by RISC activity assay in vitro. Our assays unveiled a platelet Ago2 activity that is relatively similar among all the subjects, which is in accordance with the relatively similar Ago2 expression level among healthy uraemic and dialysis donors (see Suppl. Fig. 2, available online at www.thrombosis-online.com). Altogether, our results suggest that the ability of platelets to synthesise or mediate the function of microRNAs is not affected by CKD.

Uraemic toxins that accumulate in the blood of CKD patients may nevertheless exert systemic effects, including on platelet precursor megakaryocytic cells, and influence the microRNA content of circulating platelets. Examination of the microRNA profile of platelets isolated from CKD patients identified 21 microRNAs that were differentially expressed in uraemic platelets, as compared to the healthy subjects (see Fig. 3A, left panel), thereby supporting an important alteration of the platelet microRNA profile in CKD.

When analysing the differentially expressed platelet microRNAs among our uraemic and dialysis patient cohorts (Fig. 3B), we observed that microRNAs of the same family, as exemplified by
hsa-miR-33a and hsa-miR-33b, are regulated similarly. Notably, we noted a similar trend in the level of some microRNAs deriving from both strands of a precursor in uraemic platelets. Originating from pre-miR-142, both hsa-miR-142–5p and 3p were upregulated. These tandem variations in mature microRNA expression levels are indicative of a microRNA pathway that is altered up-stream of the pre-miRNA processing step in uraemic patients. In contrast, hsa-miR-340 and –340* were altered in the opposite way, which is indicative of a differential strand selection process. Together, these observations suggest that microRNA biogenesis may be altered at multiple levels by uraemia.

**Restoration of the platelet microRNA profile upon dialysis**

Importantly, only one microRNA (hsa-miR-551b) was found to be differentially expressed in the dialysis patients cohort, as compared to the healthy cohort (Fig. 3C). Contrasting with the 21 microRNAs that are differentially expressed in platelets of uraemic patients, these results suggest that haemodialysis may restore the microRNA expression profile of platelets in patients suffering from severe CKD.
Figure 5: Platelet PCTP mRNA, whose levels are corrected by dialysis, is regulated by hsa-miR-599. A) Upper panel: Schematic representation of human PCTP mRNA with putative microRNA binding sites predicted by at least two bioinformatic programs among miRanda, TargetScan and PicTar. MicroRNAs highlighted in black are expressed in platelets. Lower panel: Topology of the interaction between hsa-miR-599 and its putative binding site, as predicted using RNA hybrid, with its calculated minimum free energy (MFE) value. B) Reporter gene activity assay. HEK293 cells were co-transfected with a pre-miR-599 expression vector and a reporter gene construct in which the sequence of PCTP 3'UTR was inserted downstream of the Rluc coding sequence. Rluc and Fluc activities were measured, and the values were normalised to those obtained with a non-relevant short hairpin expression vector (n = 4 experiments, in duplicate). ** p<0.01 (Student's paired t-test).

To verify that possibility, we analysed our microarray data with bioinformatic microRNA target predictive tools in order to identify such platelet microRNA:mRNA pairs. Among a total of 81 platelet mRNAs, whose levels were corrected by dialysis, eight mRNAs were differentially expressed in uremic patients (Fig. 4A). The level of all eight mRNAs was decreased in platelets of uremic patients. Changes in expression of the three mRNAs that were the most affected in the platelets of uremic patients, i.e. PCTP, RAB1A and ATP6V1C1 mRNAs, were validated by qPCR (Fig. 4C). For three of these eight mRNAs, we observed a concomitant decrease in the corresponding regulatory microRNAs, a direct correlation consistent with a mRNA stabilising role of microRNAs in platelets. This is the case of the following pairs: HPGD mRNA:hsa-miR-26b, COPS2 mRNA:hsa-miR-26b/hsa-miR-1297 and USP15 mRNA:hsa-miR-26b/hsa-miR-1297 (Fig. 4B).

On the opposite, the remaining 5 mRNAs showed an inverted correlation with the corresponding microRNAs, which is expected for microRNAs that regulate platelet mRNAs through destabilisation/degradation, as observed in the case of the PCTP mRNA:hsa-miR-599 pair (Fig. 4B). The level of PCTP mRNA was decreased in platelets of uremic patients, whereas that of hsa-miR-599 was increased, which is consistent with a role for hsa-miR-599 in destabilising PCTP mRNA. These changes in PCTP mRNA and hsa-miR-599 levels were corrected upon dialysis. Suggesting that the procedure helped restore their expression levels closer to those observed in healthy subjects, these data support a functional link between PCTP mRNA and hsa-miR-599.

MicroRNA regulation of platelet mRNAs in CKD

Computational analyses predicted the presence of several binding sites for microRNAs, including hsa-miR-599, in the 3'UTR of PCTP mRNA (Fig. 5A). As shown in Figure 5B, we were able to document the regulatory control of hsa-miR-599 on the PCTP 3' UTR element in cultured HEK293 cells. These results support a role for hsa-miR-599 in regulating PCTP gene expression, which may explain, at least in part, their opposite variations in expression levels in platelets of uremic and dialysis patients.

Since microRNAs may also mediate their function by interfering with mRNA translation without altering mRNA levels, and may have escaped our correlative analyses, we examined proteins whose expression was reported to be altered either in uremic or dialysis patients. Among these proteins, WD repeat domain 1 (WDR1 or AIP1) is reduced in uremic patients that display platelets defects (22). We observed no significant changes in WDR1 mRNA levels, either upon micro-array or qPCR analysis, in platelets (Fig. 6C). Bioinformatic analyses revealed that WDR1 mRNA 3'UTR harbors several putative binding sites for microRNAs, including hsa-miR-19b (Fig. 6A), whose levels are increased in platelets of uremic patients. MiR-19b expression, assessed by qPCR, confirmed that the expression of this microRNA is markedly increased in platelets of some uremic subjects (Fig. 6C).
Using a Rluc reporter gene system in cultured HEK293 cells, we confirmed the ability of hsa-miR-19b to regulate WDR1 mRNA through its 3'UTR element (Fig. 6B). Together, these findings suggest that (i) both PCTP and WDR1 mRNAs may be under microRNA control in human platelets, (ii) the deregulation of the platelet mRNA transcriptome may be linked to that of microRNAs, and (iii) alteration of this microRNA-based mRNA regulatory mechanism may underlie the platelet response to uraemia.

Discussion

Uraemic toxins that accumulate in the blood of patients suffering from CKD may affect platelet function, induce haemostatic imbalances and mediate thrombotic disorders (1, 2, 4, 8–10). These effects have been related to an alteration of the platelet proteome that is observed in these patients (21, 22). In the present study, we observed that the platelet mRNA and microRNA transcriptome was altered in CKD patients and could be restored partially upon dialysis. Known to contribute to the platelet proteome, it may be the deregulation of the platelet transcriptome that underlies, and forms the molecular basis of, platelet-related disorders in CKD patients.

The level of metallothionein-encoding genes, such as MT1X, was increased in platelets of both uraemic and dialysis patients, in which plasma zinc deficiency is common (33). Particularly abundant in platelets and involved in platelet reactivity and haemostasis (34), zinc imbalances are involved in oxidative stress (35), a state that induces expression of metallothionein genes (36). Elevated levels of platelet metallothionein genes may thus result from the altered zinc homeostasis and oxidative stress conditions that prevail in uraemic and dialysis patients, and that may contribute to the relatively high prevalence of CVD in these patients (6, 37).

Additional genes deregulated in platelets of CKD patients could be linked to platelet-related disorders observed in uraemia. For instance, the mRNA encoding for LPAR4, which is suspected to in-
hibit platelet reactivity to lysophosphatidic acid (38), is reduced by \(~\)50% in CKD patients. Lysophosphatidic acid accumulation in atherosclerotic lesions represents an important risk factor for the development of atherosclerosis and thrombosis (39), and the observed decrease in LAP4R expression in CKD patients may explain the increased risk of cardiovascular events observed in these clinical cases. We also identified genes involved in lipid metabolism, such as glycerone-acyltransferase-2 (GLYATL2), phospholipase C e1a (PLCH1), phosphatidylcholine transfer protein (PCTP), OSBP2 and SERINC1, whose levels are deregulated in uremic conditions. This may partially explain the altered synthesis of bioactive lipids (40, 41) and membrane lipid composition (42, 43) observed in platelets of uremic patients.

The conditions associated with CKD did not affect the ability of platelets to synthesise or mediate the function of microRNAs. However, we observed an important alteration of the platelet microRNA profile in uremic patients, as a total of 21, out of 247 microRNAs expressed in platelets, displayed more than two-fold changes, as compared to healthy subjects. Considering that microRNA expression in mammalian cells can be regulated at multiple steps (gene transcription, processing, transport, strand selection/separation, microRNAP assembly, stability) (44) and that uraemia is usually part of a complex clinical portrait, the aim of identifying which component(s) and/or step(s) of the platelet microRNA pathway is(are) altered in CKD patients, and how, appears to be challenging.

Correction of the level of most microRNAs and of some mRNAs, impaired in uremic platelets, upon dialysis is consistent with a mRNA regulatory role of platelet microRNAs. We were able to confirm the microRNA regulation of two mRNAs (PCTP and WDR1) that are reduced in platelets of uremic patients, the latter of which involving hsa-miR-19b. Using a proteomic approach, Marques et al. (22) demonstrated that WDR1 protein expression was reduced in platelets of uremic patients with low platelet reactivity and bleeding tendency. The fact that WDR1 mRNA levels were not altered in platelets of uremic or dialysis patients supports a role for hsa-miR-19b in repressing WDR1 mRNA translation, along a process independent of WDR1 mRNA levels (45). Interestingly, hsa-miR-19b is among a list of seven microRNAs that were identified as good predictors of platelet hyperreactivity to epinephrine (27). Upregulated by \(~\)2-fold in platelets of uremic patients, hsa-miR-19b may thus be involved in the altered reactivity of uremic platelets and the bleeding disorders observed in these patients.

When attempting to correlate platelet microRNA and mRNA levels, the caveat has to be taken into account that microRNAs may silence platelet mRNAs through translational repression (46), without inducing their cleavage and degradation. Another major limitation is the plurality of microRNA targets which, together with the functional interplay of a myriad of microRNAs that may act in concert to regulate specific platelet mRNAs, makes reliable genome-wide assessment of functionally relevant platelet microRNA:mRNA pairs almost unattainable.

Our results suggest that the biochemical conditions prevailing in patients with CKD, whether they lead to end-stage kidney failure and dialysis or not, may alter the mRNA and microRNA transcriptome of circulating platelets which, in turn, may affect platelet function and entail the development of platelet-related clinical complications, such as atherosclerosis and thrombosis. This study complements previous studies describing the relationship between platelet microRNAs and platelet reactivity (27, 47) or human diseases, including premature coronary artery disease (48). The molecular mechanisms underlying the deregulation of platelet mRNA and microRNA transcriptome in CKD patients, which may be multifaceted considering the complexity of the medical condition of these patients, warrants further investigations.
